Abstract

We consider the process of decay of symmetric vacuum state as evaporation of a Bose condensate of physical Higgs particles, defined over asymmetric vacuum state. Energy density of their selfinteraction is identified with cosmological constant Λ in the Einstein equation. Λ decay then provides dynamical realization of spontaneous symmetry breaking. The effective mechanism is found for damping of coherent oscillations of a scalar field, leading to slow evaporation regime as the effective mechanism for Λ decay responsible for inflation without special fine-tuning of the microphysical parameters. This mechanism is able to incorporate reheating, generation of proper primordial fluctuations, and nonzero cosmological constant today.

PACS: 04.20.Cv; 97.60.Lf; 98.80.Cq; 98.80.Dr; 04.70.Bw; 04.20.Bw

Any thing which contributes to the stress-energy tensor as $T_{\mu\nu} = \rho_{vac}g_{\mu\nu}$, behaves like a cosmological term $\Lambda g_{\mu\nu}$ in the Einstein equation. Developments in particles and quantum field theory, as well as confrontation of models with observations in cosmology, compellingly indicate that the cosmological constant Λ ought to be treated as a dynamical quantity (for recent review see ²⁸). At the very early stage of the Universe evolution huge value of cosmological constant is needed corresponding to $\rho_{vac} \geq \rho_{GUT}$, to drive inflation as providing the reason for the expansion of the Universe and its isotropy and large scale homogeneity ^{17,18,19,10,23,26}. Now cosmological constant is estimated from the variety of observational data at the level $\rho_{vac} \sim (0.6 - 0.8)\rho_{today}$ ^{1,27}.

Several mechanisms have been proposed involving and supporting a negative vacuum energy density growing with time to cancel initial pre-existing positive cosmological constant Λ . All those mechanisms utilize the basic property of de Sitter space-time - its quantum and semiclassical instabilities ^{33,25,15, 8,9,24,20}.

In scalar field dynamics the potential of a scalar field $V(\phi)$ plays the role of an effective cosmological constant in regimes when its derivatives are close to zero. Starting from such a regime as an initial state, field equations typically lead to successive coherent field oscillations ^{22,26}. In the context of inflationary models with effective Λ related to inflaton field in slow rolling regime, the further decay of coherent oscillations involves inflaton interactions with other fields in models of preheating ^{21,32, 5,35}.

On the other hand, we can treat the classical scalar field as the Bose-Einstein condensate of physical quanta of this field defined over its ground state (true vacuum). In our previous papers ^{11,6} it was shown that process of emergence of massive scalar particles in (from) de Sitter vacuum looks like evaporation of a Bose condensate. In our paper ¹² we proposed the model of self-consistent inflation in which the same self-interacting scalar field is responsible for both initial value of Λ and its further decay.

In the case of the Higgs field this approach involves both space-time and particle internal symmetries. In gauge theories mechanisms of spontaneous symmetry breaking imply that unbroken symmetry state is false vacuum state. At the same time this is the highly symmetric state of space-time geometry invariant under de Sitter group. In Ref.¹² we interpreted this state as Bose-Einstein condensate of physical Higgs particles whose self-interaction energy density corresponds to a scalar field potential in the state with the unbroken symmetry. The process of decay of inflationary vacuum appears then as slow evaporation of a Bose condensate responsible for inflation and further transition to the standard FRW model without special fine-tuning in initial conditions for inflation. Dynamics of the cosmological term is directly related to the hierarchy of particle symmetries breakings, which makes such an approach physically self-consistent ¹².

In the present paper we identify cosmological constant Λ with the energy density of self-interaction of scalar bosons bound in the condensate. We show the existence of the slow evaporation mechanism which seems to be generic for dynamics of Bose condensates. This mechanism for Λ decay produces an effective kinetic damping involving decoherence of coherent scalar field

oscillations due to self-interaction and back reaction of decay products.

Let us start with the simplest example of the Higgs field ϕ

$$V(\phi) = \frac{\lambda}{4}(\phi^2 - \phi_0^2)^2 \quad (1)$$

In the context of particle theories, constant part of the Higgs potential is usually omitted³⁰. However, in the cosmological context this term becomes important. In theories with spontaneous symmetry breaking the vacuum expectation value of the Higgs field, which couples to bosons and fermions to give them masses, plays the role of an order parameter. The nonzero vacuum expectation value in the asymmetric vacuum state $\langle \phi \rangle = \phi_0$, is interpreted as the development of a condensate of ϕ particles, leading to the spontaneous symmetry breaking^{22,30}.

On the other hand, ϕ particles are not physical particles, they are tachionic, with the imaginary mass, that reflects the instability of the symmetric state of the theory. In the asymmetric, physically stable vacuum state (the state with the broken symmetry) physical particles are χ particles, related to ϕ particles by $\phi = \chi + \phi_0$. It is χ particles who acquire the mass by the Higgs mechanism, and whose vacuum state is the true vacuum with zero potential and with zero expectation value, $\langle \chi \rangle = 0$. Therefore, in terms of particles χ , the true vacuum of theories with spontaneous symmetry breaking, cannot be a condensate, and we would rather have to treat the symmetric vacuum state of a theory as a condensate of χ particles in bound state. Replacing ϕ condensate by χ condensate sheds some light on the origin of Λ , which in ϕ condensate picture, where an effective Λ is related to the state of zero field¹⁹, looks mysterious. As we shall see below, in χ condensate picture effective Λ is related to nonzero value of the field χ as its energy density in symmetric state.

The Higgs field χ in this simple model is described by the Lagrangian¹²

$$\mathcal{L} = \sqrt{-g} \left[\frac{1}{2} g^{\mu\nu} \chi_{;\mu} \chi_{;\nu} - \frac{\lambda}{4} (2\phi_0 \chi + \chi^2)^2 \right] \quad (2)$$

where we dropped, for simplicity, the indices of internal variables. The potential takes the form

$$V(\chi) = \lambda \phi_0^2 \chi^2 + \lambda \phi_0 \chi^3 + \frac{\lambda}{4} \chi^4 \quad (3)$$

In the state with unbroken symmetry $\langle \chi \rangle = -\phi_0$, $\langle \chi^2 \rangle = \phi_0^2$, $\langle \chi^3 \rangle = -\phi_0^3$, and the energy density of a condensate of χ particles is given by

$$\langle V(\chi) \rangle = \frac{\lambda}{4} \phi_0^4 \quad (4)$$

We see that the constant term, playing the role of the cosmological constant Λ in the Einstein equation, is identified with the energy density of condensate of χ particles being precisely the energy density of their self-interaction.

The potential (3) describes physical particles χ with masses of Higgs bosons $m = \sqrt{2\lambda}\phi_0$, self-interacting and interacting with condensate. The term $\lambda\phi_0\chi^3$ corresponds to decay of a condensate via the channel $\phi_0 \rightarrow 3\chi$, and describes evaporation of Higgs bosons from condensate of χ particles. The term $\lambda\chi^4/4$ reproduces the runaway particle production discovered by Myhrvold²⁵. The difference from the Myhrvold result is in the origin of Λ . Gravity-mediated decay of Λ in Myhrvold approach is due to particle creation by gravitational field generated by pre-existing Λ not related to created particles. In our approach $\Lambda \sim m^2\phi_0^2$ is the energy density of self-interaction of the same particles bound within a condensate.

The Hubble parameter H during the Λ dominated stage is $H \sim \sqrt{\Lambda}$. In the context of particle theories with $\phi_0 \ll m_{Pl}$, our case corresponds to creation of bosons with $m \gg H$. Therefore our mechanism differs from that proposed by Mottola who studied creation of particles by gravitational field via the Hawking quantum evaporation which leads to the exponential suppression of masses $m \gg H$ ²⁴. In the Mottola mechanism light scalar particles with $m < H$ are evaporated from de Sitter horizon induced by pre-existing Λ . In our mechanism Higgs bosons with $m \gg H$ are evaporated from the bound state within a condensate into the free states.

Our approach differs also from Parker and Zhang theory of relativistic charged condensate as a source of slow rolling inflation²⁹. In our approach condensate of χ particles is essentially globally neutral, since it corresponds to the state with unbroken symmetry - totally symmetric state in both space-time and internal degrees of freedom¹². The condensate decays by evaporation, as well as by runaway production of χ particles which corresponds to conversion of energy of initial globally neutral state into thermal energy of χ particles.

Roughly, scenario of Λ decay looks as follows. Within a χ condensate χ particles have four-momenta $k \rightarrow 0$. Indeed, the Klein-Gordon equation for

the potential (3) in the condensate regime ($\chi = -\phi_0$; $V'(\chi) = 0$) reduces to $\ddot{\chi} + 3H\dot{\chi} + \Gamma\dot{\chi} = 0$, where Γ is a decay rate. Its solution reads $\chi = -\phi_0 - \phi_0 e^{-(3H+\Gamma)t}$. The time-dependent mode decays rapidly for any Γ stabilizing particle state in condensate with zero four-momentum ($\dot{\chi} \rightarrow 0$). This means that the χ condensate is the classical collective state within which decay of χ particles is impossible. (Their de Broglie wavelength far exceeds the horizon, so that the asymptotic states cannot be defined for the quantum transitions corresponding to decay inside a condensate.) Therefore decay of χ particles occurs in free states which correspond to the coherent field oscillations.

The fluctuations $\delta = \chi + \phi_0$ over the state with unbroken symmetry $\langle \chi \rangle = -\phi_0$ are described by the potential

$$V(\delta) = \frac{\lambda}{4}\phi_0^4 - \frac{\lambda}{2}\phi_0^2\delta^2 + \frac{\lambda}{4}\delta^4 \quad (5)$$

which reflects the instability of the state with unbroken symmetry. Wrong sign of the mass term corresponds to the excitation of the growing mode of perturbation δ over the symmetric vacuum state, leading to its decay. The evolution of fluctuations is governed by the Klein-Gordon equation

$$\ddot{\delta} + 3H\dot{\delta} - \frac{m^2}{2}\delta + \lambda\delta^3 = 0 \quad (6)$$

Let us estimate the characteristic time scale for the linear stage of development of instability, neglecting the δ^3 term and taking into account that in our case ($\phi_0 \ll m_{Pl}$)

$$\frac{m}{H} = \sqrt{\frac{3}{\pi}} \frac{m_{Pl}}{\phi_0} \gg 1 \quad (7)$$

In this approximation the solution to the Eq.(6) is given by

$$\delta(t) = C_1 e^{-\frac{m}{\sqrt{2}}t} + C_2 e^{\frac{m}{\sqrt{2}}t} \quad (8)$$

Growing mode of $\delta(t)$ corresponds to decay of condensate with characteristic timescale $\tau \sim m^{-1}$. To estimate efficiency of decay we introduce the fluctuation density

$$n_\delta = \frac{m}{4}\delta^2 \quad (9)$$

Then

$$V(\delta) = \frac{\lambda}{4}\phi_0^4 - mn_\delta + \frac{4\lambda n_\delta^2}{m^2} \quad (10)$$

The last term can be interpreted as self-interaction of fluctuations with the reaction rate $4\lambda/m^2$ leading to effective decoherence of coherent field oscillations. In the minimum of the potential (10) fluctuation density $n_\phi = m^3/8\lambda$ corresponds, by Eq.(9), to $\delta^2 = \phi_0^2$. We see that stationary distribution of fluctuations around $\delta = \phi_0$ looks like a gas of χ particles with masses $m = \sqrt{2\lambda}\phi_0$, evaporated from the state within a condensate into the fluctuations. The potential (10) achieves its minimum $V(\delta) = 0$, which corresponds to the total decay of Λ condensate into decoherent gas of χ particles, in characteristic time $\tau \sim m^{-1} \ll H^{-1}$. So, the decay of χ condensate provides the efficient mechanism for Λ decay.

We see, that identifying $V(-\phi_0)$ with the energy density of self-interaction of physical particles χ in the bound state of a Bose condensate, we can treat instability of de Sitter vacuum as dynamical realization of symmetry breaking. The process of Λ decay proceeds in this picture as the Bose condensate evaporation.

Now let us show that the effective mechanism exists related to this approach which makes the process of evaporation slow enough to guarantee e -folding needed for inflation.

Higgs bosons are generally unstable. Both χ particles and products of their decay interact with Hawking radiation from de Sitter horizon and with each other. This leads not only to decoherence of χ particles but also to appearance of relativistic particles over the condensate with the effective equation of state $p = \varepsilon/3$. Presence of relativistic gas in thermodynamic equilibrium with condensate facilitates its further decay.

The dynamical role of not exponentially small thermal component in the evolution of an inflaton field has been studied by Berera and Li-Zhi Fang³ and then incorporated into the scenario called warm inflation⁴. The classical equation of motion for a scalar field φ in the de Sitter universe reads²²

$$\ddot{\varphi} + 3H\dot{\varphi} + \Gamma_\varphi\dot{\varphi} + V'(\varphi) = 0$$

The friction term Γ_φ is introduced phenomenologically to describe the decay of the inflaton field φ due to its interaction with thermal component. Berera and Li-Zhi Fang have shown, first, that if $\Gamma_\varphi \sim H$, then thermal component can play essential role in generation of a primordial density fluctuations³. Second, in the regime $\Gamma_\varphi \gg H$ thermal component becomes dominant in the equation of motion leading to warm inflation⁴. The ques-

tion of self-consistency of this regime as governed by thermal components has been addressed in the papers ^{4,34,2}.

In our case the mechanism leading to this condition which we write as $\Gamma_\chi \gg H$ is not related to thermal components. It is related to the effective friction due to interaction of free particles with the ensemble of χ particles bound in condensate with the large occupation number, which damps oscillations and leads to stationary regime of slow evaporation of χ condensate.

Let us show that decoherence of χ particle states and back reaction of their relativistic decay products lead to the effective damping of fluctuations. The kinetic equations can be written in the standard way (see, e.g.²²). The kinetic equation describing the growth and decay of fluctuations is

$$\frac{dn_\chi}{dt} = mn_\chi - \Gamma n_\chi - n_r n_\chi \sigma - 3H n_\chi \quad (11)$$

where σ is the cross-section of the interaction of χ particles with relativistic products of their decay. In the units $\hbar = c = 1$ the reaction rate in the kinetic equations coincides with σ . The first term in the right hand side describes creation of χ particles, the second - their decay, the third - their interaction with products of decay, and the fourth - their redshifting.

The kinetic equation for products of decay, effectively relativistic matter with the equation of state $p = \varepsilon/3$, reads

$$\frac{dn_r}{dt} = -3H n_r + n_r n_\chi \sigma + \Gamma n_\chi \quad (12)$$

In the equilibrium

$$\begin{aligned} mn_\chi - \Gamma n_\chi - n_r n_\chi \sigma - 3H n_\chi &= 0 \\ -3H n_r + n_r n_\chi \sigma + \Gamma n_\chi &= 0 \end{aligned} \quad (13)$$

Decay of χ particles into light species implies $m \gg \Gamma$, which corresponds to applicability of perturbation theory for calculations of decay, and is valid in models with coupling less than the unity. Then, taking into account Eq.(7), we get

$$\rho_r = \frac{m^2}{\sigma}; \quad \rho_\chi = \frac{3mH}{\sigma} \quad (14)$$

Equilibrium density of relativistic particles ρ_r is achieved when the density of evaporated and decayed χ particles

$$\rho_{\chi d} \sim \Gamma \frac{1}{m} \rho_{vac} = \Gamma \frac{1}{m} \frac{m^2 \phi_0^2}{8}$$

satisfies the condition

$$\Gamma \frac{1}{m} \frac{m^2 \phi_0^2}{8} > \frac{m^2}{\sigma}$$

This gives the lower limit on the characteristic width of χ particles decay

$$\Gamma > \frac{8m}{\phi_0^2 \sigma} \quad (15)$$

If this condition is satisfied, the potential evolves not to the value $V(\delta) = 0$, but to the value $V_{max} - \rho_\chi - \rho_r$, becoming successively more flat. Slow evaporation of χ condensate acts in such a way to flatten the potential near its symmetric state.

We see that back reaction of evaporated particles and products of their decay produces an effective damping of scalar field oscillations which leads to effective flattening of initially nonflat potential and provides mechanism responsible for inflation without fine-tuning of the potential parameters. This is qualitatively similar to effective flattening found around spinoidal line in the Hartree-truncated theory of spinoidal inflation ⁷ (which involves fine-tuning at the slow rolling stage preceding the spinoidal regime).

The process of Λ decay is governed by the equation

$$\frac{d\rho_{vac}}{dt} = -3H(\rho_\chi + \rho_r + \frac{1}{3}\rho_r) = -4H \frac{m^2}{\sigma} \quad (16)$$

We can estimate the characteristic time of decay for two limiting cases of minimal and maximal cross-section σ . The lower limit on cross-section σ is $\sigma = 4\pi/m^2$ which is the hard ball approximation cross-section for scattering of particles of masses $m/2$. In this case

$$\frac{d\rho_{vac}}{dt} = -\frac{H}{\pi} m^4 \quad (17)$$

The law for Λ decay

$$\rho_{vac} = \rho_0 \left(1 - \frac{t}{\tau}\right)^2; \quad \tau = \sqrt{\frac{3\pi}{2}} \frac{m_{Pl} \sqrt{\rho_0}}{m^4} = \sqrt{\frac{3\pi}{32\lambda}} \frac{m_{Pl}}{m^2} \quad (18)$$

gives the e-folding number

$$H\tau = \frac{\pi}{8} \frac{1}{\lambda} \quad (19)$$

and sufficient inflation for reasonable values of coupling λ . The characteristic time for reheating is $\tau \sim \lambda H^{-1}$ and the reheat temperature $T_{RH} \sim \lambda^{1/4} m$.

The upper bound for σ is given by $\sigma = \pi/H^2$. In this case

$$\frac{d\rho_{vac}}{dt} = -\frac{4}{\pi} H^3 m^2; \quad \rho_{vac} = \frac{\rho_0}{(1 + t/\tau)^2} \quad (20)$$

where

$$\tau = \left(\frac{3^3}{2^{11}\pi} \right)^{1/2} \frac{1}{\lambda^{3/2}} \left(\frac{m_{Pl}}{\phi_0} \right)^4 \tau_{Pl} \quad (21)$$

The e-folding number is then

$$H\tau = \frac{3}{32} \frac{1}{\lambda} \left(\frac{m_{Pl}}{\phi_0} \right)^2 \quad (22)$$

and, for the considered case $\phi_0 \ll m_{Pl}$, inflation is sufficient for any λ . Reheating temperature is $T_{RH} \sim \lambda^{1/4} H$.

More detailed investigation of dynamics of a vacuum decay needs particular model for calculating σ , but the results will be within the range between the cases of minimal and maximal σ . For example, the picture of evaporation investigated in the Ref.¹¹ corresponds to the case of evaporation of Higgs bosons and their reheating to the Hawking temperature $T_{RH} \sim H$ ¹⁶. The rate of Λ decay is given in this case by

$$\frac{d\rho_{vac}}{dt} = -3Hm(mH)^{3/2} \quad (23)$$

Here we considered Λ decay in the case of vacuum dominance. When radiation density starts to exceed vacuum density at the last stage of evaporation we would have to change the equation (16) taking into account the evolution of Hubble parameter as well as of matter and radiation density, which in the standard FRW cosmology evolves as t^{-2} . The Eq.(20) reproduces this behaviour starting at the stage of vacuum dominance for the case of maximum possible cross-section σ . Provided that this behaviour remains dominating at successive stages, this corresponds to the existence of remnant

evaporating condensate today with the density comparable to the total density in the Universe which seems to agree with results of recent analysis of observational data ¹.

The generalization of this approach to the case of arbitrary scalar field potential is straightforward. Any cosmologically reasonable potential must satisfy the condition $V(\phi^2 - \phi_0^2) > 0$. True vacuum state $\langle \phi \rangle = \phi_0$ is determined as the minimum of the potential $V = 0$. The physical particles $\chi = \phi - \phi_0$ are defined over the true vacuum state. Their mass is given, as usual, by $\partial^2 V / \partial \phi^2$. Any state with $V(\chi) > 0$ we can treat as bound state of χ particles trapped inside a Bose condensate. The equilibrium fluctuations density corresponds to deviation of the potential from its initial value at the given point by the quantity $\rho_\chi + \rho_r$ (see Eq.(14)). It means that in a characteristic time m^{-1} the field is not completely moved to its ground state, but, instead, is stabilized near its initial value having slightly changed by the magnitude $\rho_\phi + \rho_r \ll V(\chi)$.

We see that the decoherence of χ particles and the back reaction of their decay products leads to effective freezing of the field near its initial value. Near this value the potential becomes locally flat, and the energy density of condensate of χ particles starts to play a role of an effective cosmological constant. It realizes the case of chaotic inflation for initially nonflat potential in the case $m \gg H$ and $\phi_0 \ll m_{Pl}$.

At the first sight, the appearance of slow evaporation regime in our approach seems to lead to the same spectrum of initial density fluctuations as in slow rolling models. However, the origin of fluctuations is different. In our case fluctuations are generated by statistical distribution of evaporated particles, while in the typical slow rolling picture they originate from nonsimultaneous transitions to the ground state. We are currently investigating this problem and we expect "blue" spectrum of density fluctuations, which seems to be favored by theories of large scale structure formation.

Formally the mechanism presented in this paper is based on rather trivial solution ($\phi \simeq const$) of scalar field dynamics, which however appears to have nontrivial consequences leading to kinetic equilibrium regime for slow evaporation of Bose-Einstein condensate. This kind of solution has analogies in experimentally studied Bose-Einstein condensation in atomic physics ³¹.

The case of Higgs field considered here is the simple illustration of the proposed mechanism of Λ decay, which seems to be more generic and to work also in non-Abelian gauge models without Higgs mechanism, in which

symmetry breaking is induced by nonlinearity of gauge interactions as in technicolor models.

Let us summarize. The kinetics of the Bose condensate evaporation can effectively damp the coherent field oscillations leading to slow evaporation regime for wide range of possible particle interaction parameters. In the cosmological context this provides the effective mechanism for Λ decay responsible for dynamics of symmetry breaking, which can incorporate inflation, reheating, as well as nonzero cosmological constant today. Currently we are working on rigorous justification of the existence of this mechanism in the frame of quantum field theory ¹³.
